CHANGING QUALITY OF SERVICE FOR VOICE OVER IP CALLS

TECHNICAL FIELD OF THE INVENTION

The present invention is related to telecommunications. More
5 particularly, the present invention is related to methods for
changing quality of service for Voice over IP communications.

BACKGROUND

Information technology (IT) and Communication Networks (Networks) provide end users with access to communications and diverse media. Typical Networks include, for example: PSTN (Public Switched Telephone Network), IP-based (Internet Protocol, or Internet), ISDN (Integrated Services Digital Network), and PLMN (Public Land Mobile Network). Networks provide end users with diverse applications such as: wired and wireless voice, multimedia access/transmission, Internet access, Voice over IP (Internet Protocol), etc. Access to and communication over Networks is accomplished via hardware (e.g., switches, routers, servers, gateways, gateway controllers, etc.). and communications protocols (e.g., IP (Internet Protocol), RLP (Radio Link Protocol), ATM (Asynchronous Transfer Mode), GSM (Global System for Mobile Communication), CDMA (Code Division Multiple Access), TDMA (Time Division Multiple Access), RTP (), SS7 (Signaling System 7), SIP (Session Initiation Protocol), MGCP (Media Gateway Control Protocol), etc.).

A Network link may generally be set up by using access technology, such as PRA (Primary Rate Access) signaling or ISUP (ISDN user part). Functionality to set up links between, for example, a Media Gateway (MG) and the Internet, normally reside on

a separate hardware component such as an Access Server (AS). Once the AS gets signaled by the Mobile Switching Center (MSC), an incoming communication requesting access is directed from the MSC towards the Media Gateway Controller (MGC). Once the MGC gets signaled via a communication requesting Internet access, the MGC seizes AS functionality.

Internet applications such as IA (Internet Access), VoIP (Voice over IP) and Multimedia generally require certain functionality such as contained within a MGC to control the media stream in the MG as well as other Internet specific functionality such as AAA (Authentication, Authorization, Accounting).

Networks access and operational inefficiencies generally occur because of bandwidth limitations or hardware clashes. For example, a traditional telephone call is established over a dedicated network circuit (e.g., Public Service Telephone Network, or "PSTN"). Regardless of the amount of voice data (e.g., analog voice signals) to be transferred across the circuit connection (e.g., via the PSTN), the entire circuit must generally be dedicated for the duration of the call; thus resulting in a potentially low overall usage of switching resources. An alternative to circuit switched (voice) calls is packet switched calls (e.g., voice over IP). In a packet switched call, the voice

data is encoded into packets which are then directed across a network and reassembled into an approximation of the original data at the receiving end. During a silent period of a call, no data generally needs to be packetized and transmitted across the network; thus saving network resources and allowing for higher call density (e.g., more calls can be routed on the same amount of network resources).

In order for a call to be sent over a packet-switched network, the voice data (e.g., analog voice signals) must be sampled and converted into a digital format (e.g., packetized voice). The sampling process introduces a trade-off between sound quality and bandwidth utilization. A voice stream can generally be sampled very frequently to produce very high sound quality on the receiving end, but at the cost of using a large amount of bandwidth to transport generated packets. Alternatively, voice can be sampled infrequently to produce a smaller amount of packet data but at the cost of low sound quality at the receiving end.

As part of setting up a call over a packet network, a codec (coding/decoding algorithm) must generally be specified to control what rate of sampling is used to encode the call. Depending on the codec algorithm specified, various levels of voice quality/ bandwidth utilization can be generally achieved.

There is apparently a lack of available methods and systems for a caller making a call on a voice over IP network to specify, during a call, a level of voice quality or Quality of Service (QoS) that is desired. While the network operator can generally specify at initial call setup or even in mid-call what quality level will be used, the caller apparently cannot. Such a lack of user control over QoS precludes the network operator from offering low Quality of Service (QoS) at a low cost while still allowing the caller to upgrade to a higher QoS at a higher cost as needed during, or for the remaining duration of, a voice communication.

SUMMARY OF THE INVENTION

Aspects of the present invention provide methods and/or systems whereby a subscriber making a call on a Voice over IP network can choose a QoS during an ongoing voice communication, and may be realized over numerous network configurations so long as the configuration provides for: packetization of voice streams over an IP network using a codec; codec choices; the ability to change a codec in use during an ongoing call; and the ability for the caller to signal the network (e.g., through in-band DTMF (dual tone multifrequency) commands via digit collection and/or through a flash feature) when a change of codec (coder/decoder) algorithm is desired.

One aspect of the invention provides a method for changing QoS for voice over IP communication wherein caller invoked signaling of a network controller indicates that a change in QoS is desired during an ongoing voice over IP communication; and system implementation of a change in QoS is provided through packetization or depacketization of a communication in response to the caller invoked signaling.

Another aspect of the present invention provides a system for changing QoS for voice over IP communications. A signal monitoring module for monitoring subscriber inputs representing requests for

a QoS change; and a controller for implementing subscriber inputs representing requests for a QoS change.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 illustrates voice over IP call flow and environment;
and

Figure 2 illustrates voice over IP call flow and environment
5 wherein a change in QoS is specified.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Referring to Figure 1, both the signaling and voice paths for a typical voice (e.g., PSTN-based communication) over IP (e.g., data network-based communication) phone call are illustrated. It should be appreciated that PSTN is referred to herein by example only and should not be taken as a limitation of the voice communication aspects invention.

Referring to Figure 1, the following numbered events generally occur during the creation of a voice over IP (VoIP) call:

- 1 A user dials a number from the originating PSTN phone 101.
- 2 The PSTN network 103 on the originating side signals (e.g., using the SS7 signaling protocol) the originating Media Gateway Controller (MGC) 105 that a VoIP connection is requested.
- 3 The originating MGC 105 signals (e.g., using the Media Gateway Control Protocol (MGCP)) the originating Media Gateway (MG) 107 instructing it to allocate encoding and IP resources to handle the originating side of the call.
- 4 The originating MGC 107 signals (e.g., Session Initiation Protocol (SIP)) the terminating MGC 109 to set up the terminating side of the call.

5 The terminating MGC 109 signals (MGCP) the terminating MG 111 instructing it to allocate decoding and IP resources to handle the terminating side of the call.

6 The terminating MGC 109 signals (e.g., SS7) the
5 terminating PSTN network 113 to terminate a call to the terminating PSTN phone 115.

7 The originating MG 107 encodes voice stream into IP packets and transmits (e.g., utilizing Real Time Protocol (RTP)) the IP packets over a data network (e.g.,
10 Internet) 119 to the terminating MG 111, where the terminating MG 111 decodes the packets into a voice stream and presents the stream to the terminating PSTN network 113 which carries it to the terminating PSTN phone 115.

15
In the basic call flow, once a call is established, the originating and terminating MGs 107/111 generally encode and decode the voice stream with a common codec (coder/decoder) algorithm stored within codec modules 117 and 118 located within MGs 107 and
20 111, respectively, throughout the duration of the call. With the application of the invention, the codec algorithm in use can be changed during the call by the person who originated the call.

Referring to Figure 2, signaling and voice paths are shown where the steps that are generally needed in order for the caller to change the codec 217 during the call are implemented. The following steps are followed during call setup:

- 5 1 A user dials a number from originating PSTN phone 201.
- 2 The PSTN network 203 on the originating side signals the
 originating Media Gateway Controller (MGC) 205.
- 3 The originating MGC 205 signals the originating Media
10 Gateway (MG) 207 instructing it to allocate encoding and
 IP resources to handle the originating side of the call.
- 4 The originating MGC 205 signals the terminating MGC 209
 to set up the terminating side of the call.
- 5 The terminating MGC 209 signals the terminating MG 211
15 instructing it to allocate decoding and IP resources to
 handle the terminating side of the call.
- 6 The terminating MGC 211 signals the terminating PSTN
 network 213 to terminate a call to the terminating PSTN
 phone 215.
- 7 The originating MGC 205 signals the originating MG 207
20 instructing the MG 207 to notify the MGC 205 if the
 originating caller dials the change QoS key sequence on
 the phone 201.

8 The originating MG 207 encodes the voice stream into IP
packets and transmits the IP packets to the terminating
MG 211. The terminating MG 211 decodes the packets into
a voice stream and presents the stream to the terminating
5 PSTN network 213 which carries it to the terminating PSTN
phone 215.

9 Once the call is established, the originating MG 207
monitors for the originating caller's entry of the change
QoS key sequence.

10
Assuming the above steps were followed, the originating MG 207
may monitor for caller entered command (e.g., keystrokes)
indicating he or she wants to change QoS.

When the caller enters the specified keystrokes, the QoS for
15 the call is changed in the following way:

- 1 The originating MG 207 receives the user's dialed change
QoS key sequence (e.g., a sequence such as "##4").
- 2 The originating MG 207 signals the originating MGC 205
that "##4" has been entered.
- 20 3 The originating MGC 205 interprets the, "##4" to mean
"change quality of -service, to level four" and signals
the, originating MG 207 to change the codec algorithm

within codec module 217 to a codec algorithm that is supported by the receiving MG 211 codec module 218 (e.g., that is of "level four"). The mapping from "level four" to one of the available codecs algorithms should be implementation dependant.

4 The originating MG 207 changes the codec algorithm and continues transmitting media packets to the terminating MG 211.

5 The terminating MG 211 determines the new codec algorithm from data contents of the packets it is receiving. It changes codec algorithm within codec module 218 to match and the call continues with the, new codec algorithm implemented by codec module 217.

15 By further example, a long distance carrier may accept calls from the PSTN and carry them across an IP network. By default, the calls are generally at the lowest QoS available and at the cheapest rate. After the call is connected, the caller may upgrade the QoS by entering a code (e.g., "##n") at the terminal keypad. Once the user changes QoS, they can be billed at a higher rate for the duration of the call (or until the QoS is reduced).

Monitoring for caller commands is provided via a DTMF (dual tone multifrequency) monitoring module that may be associated with the MG 207. The DTMF module monitors the caller line for DTMF commands. Monitoring of the callers line may be continuous, which
5 is resource intensive, or upon a caller invoked flash signal prior to entering commands at the terminal 201 keypad.

How an originating MG would monitor for the change QoS key sequence and signal the originating MGC with the received keys has been described. Alternatively, the MGC could instruct the MG at
10 the beginning of the call how to handle the change QoS key sequence when the MG detects it. The MG would then perform the required action when it detects the QoS key sequence, and not signal the MGC.

In addition to simply changing the codec in use, the
15 originating MG can be instructed to set a Type of Service (ToS) value in the IP packets it is sending to the terminating MG. For purposes of the following claims of the invention, QoS should be interpreted to also mean ToS. Routers in the IP network can interpret the ToS value to give priority to certain packets so they
20 arrive at the MG more reliably. Giving the foregoing teachings, it should be appreciated that the invention is widely applicable. For example, in a 3G digital cellular network, the caller (or the

receiver) may choose to upgrade (or downgrade) the QoS used by the air interface. By upgrading, the caller uses more air resources, but pays a premium. By downgrading, the caller uses less air resources, but pays a lesser rate.
